ABSTRACT

Running compute-intensive or blocking I/O operations in the UI event thread of smartphone apps can severely degrade responsiveness. Despite the fact that Android supports writing concurrent code via AsyncTask, we know little about how developers use AsyncTask to improve responsiveness. To understand how AsyncTask is used/underused/misused in practice, we first conduct a formative study using a corpus of top 104 most popular open-source Android apps comprising 1.34M SLOC. Our study shows that even though half of the apps use AsyncTask, there are hundreds of places where they missed opportunities to encapsulate long-running operations in AsyncTask. Second, 46% of the uses are manually refactored. However, the refactored code contains concurrency bugs (such as data races) and performance bugs (concurrent code still executes sequentially).

Inspired by these findings, we designed, developed, and evaluated ASYNCHRONIZER, an automated refactoring tool that enables developers to extract long-running operations into AsyncTask. ASYNCHRONIZER uses a points-to static analysis to determine the safety of the transformation. Our empirical evaluation shows that ASYNCHRONIZER is (i) highly applicable, (ii) accurate, (iii) safer than manual refactoring (iv) it saves development effort, (v) its results have been accepted by the open-source developers. This shows that ASYNCHRONIZER is useful.

General Terms: Refactoring

Keywords: Asynchrony, Android, AsyncTask

1. INTRODUCTION

For smartphone apps, responsiveness is critical. The apps can easily be unresponsive because mobile devices have limited resources and have high latency (excessive network accesses). With the immediacy of touch-based UIs, even small hiccups in responsiveness are more obvious and jarring than when using a mouse or keyboard. Some sluggishness might motivate the user to uninstall the app, and possibly submit negative comments in the app store.

Previous research [35, 49] shows that many Android apps suffer from poor responsiveness and one of the primary reasons is that apps execute all workload in the UI event thread. The UI event thread of an Android app processes UI events, but long-running operations (i.e., CPU-bound or blocking I/O operations) will “freeze” it, so that it cannot respond to new user input or redraw. Android documentation [1] warns that developers should not use long-running operations in the UI event thread.

The primary way to avoid freezing the UI event thread is to resort to concurrency, by extracting long-running operations into a background thread. While programmers can use java.lang.Thread to fork concurrent asynchronous execution, it is cumbersome to communicate with the main thread. Android framework provides a better alternative, AsyncTask, which is a high-level concurrent construct. AsyncTask can also interact with the UI thread by updating the UI via event handlers. For example, the event handler onPostExecute executes after the task is finished, and can update the UI with the task results.

In this paper we first present a formative study to understand how developers use AsyncTask. We analyzed a corpus of top 104 most popular, open-source Android apps, comprising 1.34M SLOC, produced by 1139 developers. The formative study answers the following questions:

RQ1: How is AsyncTask used? We found that 48% of the studied projects use AsyncTask in 231 different places. In 46% of the uses, developers extracted long-running operations into AsyncTask via manual refactoring. In the remaining cases, they used AsyncTask from the first version.

RQ2: How is AsyncTask misused? We found two kinds of misuses. First, in 4% of the invoked AsyncTask, the code runs sequentially instead of concurrently: the code launches an AsyncTask and immediately blocks to wait for the task’s result. We found similar problems in our previous studies on concurrent libraries in C# [38, 39]. Second, we found that in 13 cases, code in AsyncTask accesses GUI widgets in a way which is not thread-safe. This leads to data races on these GUI widgets.

RQ3: Is AsyncTask underused? We found that 251 places in 51 projects execute long-running operations in UI event thread. This also confirms the findings of a recent study by Liu et al. [35] that shows that 21% of reported responsiveness bugs in an Android corpus arise because de-
Formative study:
To the best of our knowledge, this paper presents the first study on the usage, misusage, and underusage of Asynchonizer in Android apps.

Algorithms:
We designed an automated refactoring tool that addresses the challenges of refactoring long-running operations into Asynchonizer. The algorithms account for inversion of control by transforming sequential code into callback-based asynchronous code, and reason about non-interference of updates on shared variables.

Tool:
We implemented the refactoring approach, specialized to Asynchonizer. We implemented it as an extension of the IteRace [41] refactoring engine. This paper makes the following contributions:

3. **Tool:** We implemented the refactoring approach, specialized to Asynchonizer. We implemented it as an extension of the IteRace refactoring engine. This paper makes the following contributions:

4. **Tool Evaluation:** To evaluate Asynchonizer’s usefulness, we used it to refactor 135 places in 19 open-source Android apps. We discovered and reported 169 data races.

BACKGROUND ON ANDROID

2.1 Android GUI Programming

Android GUIs are typically composed of several activities. An activity represents a GUI screen. For example, the login screen of an email client is an activity. An application GUI transitions through a sequence of activities, each of which is independent of the others. However, at any given time, only one activity is active. Activities contain GUI widgets.

Similarly to many other GUI frameworks such as Swing [7] and SWT [9], Android uses an event-driven model. Events in Android apps include lifecycle events (e.g., activity creation), user actions (e.g., button click, menu selection), sensor inputs (e.g., GPS, orientation change), etc. Developers define event handlers to respond to these events. For example, onCreate handler is invoked when an activity is created, while onClick handler of a button is invoked when a button is clicked.

Android framework uses a single thread model to process events [1]. When an application is launched, the system

```java
public class MainActivity extends Activity {
    public boolean onOptionsItemSelected(MenuItem item) {
        ...
    }

    new Button(new OnClickListener() {
        public void onClick(...) {
            execute((Void)null);
        }
    });

    protected void onPreExecute(String filename) {}
    protected void onPostExecute(String filename) {}
    protected void onProgressUpdate(Void... values) {}
    protected void onCancelled (String filename) {}
}
```

The tool and experimental subjects are available at:

http://refactoring.info/tools/asyncronizer

transitions through a sequence of activities, each of which is independent of the others. However, at any given time, only one activity is active. Activities contain GUI widgets.

Similarly to many other GUI frameworks such as Swing [7] and SWT [9], Android uses an event-driven model. Events in Android apps include lifecycle events (e.g., activity creation), user actions (e.g., button click, menu selection), sensor inputs (e.g., GPS, orientation change), etc. Developers define event handlers to respond to these events. For example, onCreate handler is invoked when an activity is created, while onClick handler of a button is invoked when a button is clicked.

Android framework uses a single thread model to process events [1]. When an application is launched, the system
creates a main thread, i.e., the UI event thread, in which it will run the application. This thread is in charge of dispatching UI events to appropriate widgets or lifecycle events to activities. The main thread puts events into a single event queue, dequeues events, and executes event handlers.

However, if the main thread executes CPU-intensive work or blocking I/O calls such as network access or database queries, this results in poor responsiveness. Once the main thread is blocked, no events can be dispatched and processed, so application will not be responsive to users’ actions. To avoid unresponsiveness, developers should exploit concurrency and extract long-running operations into another thread.

### 2.2 AsyncTask in Android Framework

To ease the use of concurrency, Android framework provides AsyncTask class. AsyncTask is a high-level abstraction for encapsulating concurrent work. AsyncTask also provides event handlers such as onPostExecute that execute on the main thread after the task has finished. Thus, the background task can communicate with the main thread via these event handlers.

We illustrate a typical usage of AsyncTask using a real-world app, KeepScore, that keeps scores for games that require tallying points as one plays. Figure 1 shows an AsyncTask that reads game scores from a database and exports them in a spreadsheet file. The methods that start with “on” are event handlers. Figure 2 shows the flow of this AsyncTask.

Line 4 sets up a listener for a button, and when the button is clicked, method exportToSpreadsheet is called. This method creates an AsyncTask (line 12) and executes it concurrently with the main thread. The doInBackground method (line 14) encapsulates the work that executes in the background. The task queries a database and adds the results to a list, games (line 17). Finally, the result of the background computation is returned for main thread to use (i.e., filename at line 21).

While the task is executing, it can report its progress to the main thread by invoking publishProgress and implementing onProgressUpdate handler. In the example, the task publishes its progress every time it finds a game (line 18), so the main thread can update a progress dialog (line 24). The main thread executes the onPostExecute handler after doInBackground finishes. In this example, the handler updates the GUI by dismissing the progress dialog (line 27). Notice that this handler takes the result of the task as parameter (filename at line 26).

When it manages the lifecycle of an AsyncTask, the main thread executes onPreExecute (line 13) before the doInBackground. It also executes the onCancelled (line 29) when the task is cancelled.

The three generic types of AsyncTask (line 12) represent the parameter types of doInBackground onProgressUpdate, and the return type of doInBackground.

Notice that there are two ways that the main thread can fetch the result of an AsyncTask. One, the result is available in the onPostExecute. Second, the result can be explicitly requested through the get method on the task. This method has blocking semantics: if the result is available, it will return immediately, otherwise it will block the main thread until the result becomes available.

### 3. FORMATIVE STUDY OF ASYNCTASK USE

In this section we present our formative study to understand how developers use, misuse, and underuse AsyncTask in open-source Android apps.

#### 3.1 Experimental Setup

Corpus of Android Apps. We selected our corpus of Android apps from Github [6] to find Android apps, we filter Java repositories by searching if their README file contains “Android app” keyword. We also manually confirmed that these repositories are Android apps. We apply two more filters. First, because we want to contact developers, we need to avoid analyzing inactive projects. Thus, we only keep repositories that contain at least one commit after June 2013. Second, because we want to study the usage of AsyncTask in mature, representative apps, we ignore apps that have less than 500 SLOC. Also, we ignore all forked applications since they are similar to the original repository. Finally, we use the top 104 most popular projects as our corpus, comprising 1.34M SLOC, produced by 1139 developers.

Analysis. We want to study whether developers refactor existing code into AsyncTask (i.e., they encapsulate existing statements into AsyncTask), or whether they introduce AsyncTask on new code they write from scratch. Thus, we study not the latest version of the code which contains AsyncTask, but the first version of the code where developers introduce this construct. To do this, we searched the commit history of our corpus through GITective API [5], identified the commits that add import statements to AsyncTask, and manually inspected the versions before and after such commits. This helps us understand questions about correct and incorrect usage.

To understand whether the corpus contains underusage of AsyncTask, we want to identify long-running operations that execute in the UI event thread and are potentially decreasing the responsiveness of the application. These operations are candidates to be encapsulated within AsyncTask.

Thus we first created a “black list” of long-running operations that Android documentation [1] warns should be avoided in the UI. We used Eclipse’s search engine to find call sites to such operations. Using the call graph hierarchy, we analyzed whether they appear directly or indirectly in event handlers but not in AsyncTask or Thread.

To assure validity and reliability, we make all the data-set and the results available online [2].

#### 3.2 Results

Table 1 shows the results about usage and misusage in the 50 projects that use AsyncTask. The second row shows the items we count, including the number of instances of AsyncTask (column 2), how many event handlers of AsyncTask are implemented by developers (columns 3 to 6), number of misuse which includes accessing GUI in doInBackground (column 7) and wrong usage of get (column 8). The third row counts these items in newly introduced AsyncTask (i.e., code where developers use AsyncTask from scratch). The fourth row counts these items in code that was manually refactored by developers to use AsyncTask. The fifth row sums the usage in newly introduced and refactored AsyncTask.

Using the data in Tab. 1, we answer three questions:

**RQ1: How is AsyncTask used?**

50 out of 104 projects use AsyncTask to embrace concurrency. This shows AsyncTask is adopted in Android apps.
We found that 51 out of 104 projects call long-running APIs.

We found that 13\% of projects have already used `AsyncTask`.

Thus, such usage blocks the main thread immediately and is widely implemented by developers (81\% (187 out of 231)). This is reasonable since 54\% (125 out of 231) of `AsyncTask` instances are newly introduced when developers add new features. However, there are 46\% (106 out of 231) `AsyncTask` refactored. Here we found two refactoring scenarios. First, in 94 cases, the code was refactored directly into `AsyncTask`. Second, in 12 cases, the code is refactored from Java `Thread` into `AsyncTask`. This is reasonable since `AsyncTask` provides event handlers and is easier to use than `Thread` when the background thread needs to communicate with the main thread.

Lastly, we notice that `onPostExecute` handler is the most widely implemented by developers (81\% (187 out of 231)). However, for the other three handlers, the implementation percentage is only 23\%, 4\% and 3\%. A possible explanation is that after a task is done, applications have to update UI and report the result to users. `onPostExecute` handler provides an easy way to update UI without explicitly knowing when the task is finished, so it is implemented in most cases.

**RQ2: How is `AsyncTask` misused?**

We found that 13 `AsyncTask` (7 in manual refactoring) access GUI in `doInBackground`. However, based on the Android document, accessing GUI from outside main thread will lead to races, because Android UI toolkit is not thread-safe.

Data races can also occur on the non-GUI objects after developers transform sequential code to concurrent code. Figure 3 shows a manual refactoring in `ChatSecureAndroid` project. At line 19, `AsyncTask` handler eventually calls `startGroupChat` method, in which an `AsyncTask` is executed. This task writes to field `mRequestedChatId` at line 17. However, this field is read at line 4, which can be executed concurrently with line 17. Thus, there is a race on `mRequestedChatId`. Note that this data race is found by `Asynchronizer` in our evaluation (see Sec. 6) rather than being found manually in this formative study.

Also, nine manually refactored `AsyncTasks` are misused because developers invoke `get` method on the task immediately after starting the task. As we mentioned in Sec. 2, invocation of `get` blocks the current thread until the result is available. Thus, such usage blocks the main thread immediately and defies the purpose of using `AsyncTask`.

**RQ3: Is `AsyncTask` underused?**

We found that 51 out of 104 projects call long-running APIs in UI event handlers at 251 places. In these 51 projects, 17 projects have already used `AsyncTask`. Still, we found 79 places where `AsyncTask` is underused. The remaining 34 projects never use `AsyncTask`.

<table>

<td>9</td>
</tr>
</tbody>
</table>

Based on our findings for RQ1, we conclude that `AsyncTask` is widely adopted and developers manually refactor their code to use `AsyncTask` in many cases. However, as RQ3 shows, `AsyncTask` is still underused. RQ2 shows that manual refactoring may introduce bugs.

Based on the results for RQ1–RQ3, we conclude that there is a need for safe refactoring tools to enable developers to transform code towards `AsyncTask` (presented in Sec. 4), as well as help developers check possible races that can occur between the code running in `AsyncTask` and the code running in the main thread (presented in Sec. 5).

### 4. TRANSFORMATIONS

This section describes the code transformation that enables developers to move code from main thread into `AsyncTask`. We implement the transformation in our tool, `ASYCHRONIZER`. We first explain the overall workflow of the tool, and then illustrate the transformations.

#### 4.1 Refactoring Workflow and Preconditions

We implement `ASYCHRONIZER` as a plugin in the Eclipse IDE [3]. To use `ASYCHRONIZER`, the programmer selects statements that she wants to encapsulate within `AsyncTask`, and then chooses the `CONVERT TO ASYNC TASK` option from the refactoring menu. The programmer can also specify the class and instance name that `ASYCHRONIZER` will use to generate `AsyncTask`. `ASYCHRONIZER` moves the selected statements into `AsyncTask.doInBackground` method. In addition, `ASYCHRONIZER` also infers the subsequent statements that can be moved to `onPostExecute`. Before applying the changes, `ASYCHRONIZER` gives the programmer the option to preview them in a before-and-after pane. Then, `ASYCHRONIZER` transforms the code in place.

After the transformation, the programmer can invoke `ASYCHRONIZER`’s safety analysis component to check data races due to the transformation. We will present the safety analysis in Sec. 5. If `ASYCHRONIZER` found data races, the programmer still needs to confirm and fix them manually. Only after this the refactored code is correct.

Figure 4(a) shows a code snippet from an Android app, `GR-Transit`, that displays bus routes and schedules. The

<td>9</td>
</tr>
</tbody>
</table>
code snippet is used to show the bus routes that pass a given bus stop. If the programmer applies our transformation to lines 21 to 23, **Asynchronizer** will transform the code to Fig. 4(b). In a subsequent version of **GR-Transit**, the programmers have done this transformation manually. Their new code, modulo syntactic difference, is the same as **Asynchronizer**’s output.

**Asynchronizer** checks the following three preconditions before transforming, and reports failed preconditions:

**P1** The selected statements do not write to more than one variable which is read in the statements after the selection. Such a variable needs to be returned by `doInBackground`, but Java methods can only return one single variable.

**P2** The selected statements should not contain `return` statements. A `return` statement in the original code enforces an exit point from the enclosing method. However, the same `return` statement extracted into an **AsyncTask** can no longer stop the execution of the original method. Similarly, the `break` and `continue` statements are only allowed if they are selected along with their enclosing loop.

**P3** The selection contains only entire statements. Selecting an expression that is part of a statement is not allowed because it would force the **AsyncTask** to immediately invoke the blocking `AsyncTask.get()` to fetch the expression; this defies the whole purpose of launching an **AsyncTask**.

### 4.2 Create the `doInBackground` Method

The first step of the transformation is to move the selected statements into the `doInBackground` method. This is similar to **EXTRACT METHOD** refactoring. In this step, **Asynchronizer** needs to determine the arguments and the return value of `doInBackground`. The arguments are the local variables which are used in the selection but declared before it. The return value is the local variable which is defined in the selection but used after it.

In Fig. 4(b), the `doInBackground` method takes two arguments, `qry` and `selectargs`, and returns `mCsr`. However, note that `doInBackground` has only one `variableargs` parameter (i.e., array of unknown length), and its type is specified by the type argument (generic) of **AsyncTask**. If all local variables are of the same type, **Asynchronizer** sets this type as the first generic type argument for **AsyncTask**. If the passed-in local variables are of different types, as it is the case for our example, **Asynchronizer** uses `java.lang.Object` as the generic type argument (Fig. 4(b) line 18), and dereferences and type-casts the parameters (Fig. 4(b) lines 19 and 20). If `doInBackground` has no arguments or return value, it uses `null` as parameter type or return type, and returns `null`.

### 4.3 Create `onPostExecute` Handler

The second step is to infer which code can be put into `onPostExecute` handler. Because the Android framework in-
volves the `onPostExecute` after the method `doInBackground` has finished, the analysis needs to determine that the statements inside these two methods follow the same control-flow as in the original program. Otherwise, the refactored program will have a different semantics.

A naive implementation is to move all the statements after the selected code into `onPostExecute`. However, this may break the control flow of the main thread. A statement cannot be moved if it is not dominated by the statements in the selected code, or if it is a `return` statement. A statement `dominates` [11] another if every path from the entry point to the latter statement passes through the former statement.

Algorithm 1 infers the set of statements to be moved to `onPostExecute`. The inputs of the algorithm include the selected code that will be put into `doInBackground` (`selected`), the list of statements syntactically after the selected code (`post`), and the return variable of `doInBackground` (`rv`). The output is the set of statements which can be moved to `onPostExecute` (`moved`). `unmoved` contains the statements which cannot be moved.

The algorithm first selects the prefix of `post` in which all statements are dominated by `selected` and do not `return` (lines 3 to 9). The remaining statements cannot be moved so they are put into the `unmoved` variable (line 10). The algorithm then constructs the final result as the prefix of `dominated` for which all statements have no effect on any statement in `dominated` (lines 11 to 18). This ensures no data dependencies are broken. `unmoved` is updated with any statements which are not in `moved` (line 19). Finally, if `unmoved` contains statements that use the resulting value of `doInBackground`, `AsyncRacer` adds a call to `AsyncTask`'s `get` method before the first such use (lines 20 to 22).

In the example shown in Fig. 4(a), all the statements after the selected code (lines 27 to 35) can be put into `onPostExecute`. However, suppose there was a statement at line 36 that throws exceptions (e.g., programmer selects `FileOutputStream.write` method which throws `IOException`). `AsyncRacer` needs to generate try-catch block to handle the exceptions. `AsyncRacer` first collects the exceptions that are declared to be thrown by the selected code. If these exceptions are caught in the original refactored method, it copies the corresponding catch clauses into `doInBackground` or `onPostExecute` to handle the exceptions. Otherwise, it generates empty catch clause. In our experiment, all the cases that throw exceptions have corresponding catch clauses in the original code.

(S2) The original code may use `this` or `super` pointer (Fig. 4(a) line 34). After moving it to an inner `AsyncTask` class, our tool replaces the original pointer with outer class’ `this` or `super` pointer (Fig. 4(b) line 34).

## 5. DATA RACE CHECK

Our formative study (Sec. 3) shows that developers do introduce data races when they manually refactor sequential code into `AsyncTask` concurrent code. These data races are either accesses to GUI elements from the `doInBackground`, or possibly concurrent accesses to other shared resources. Data races are hard to find as they only manifest themselves under certain thread schedules. To assist developers with the refactoring, we propose a static race detection approach specialized to the thread structure generated by `AsyncTask`. We implement our approach as an extension of the `IReace` race detector [41].

`IReace` is a static race detector for Java parallel loops that achieves low rates of false warnings by taking advantage of the extra semantic information provided by the use of high-level concurrency constructs. It uses the known thread-safety properties of concurrent collection classes, summarizes races that occur in libraries at the level of the application, and specializes for the thread structure of lambda-style parallel loops.

While `IReace` is only capable of analyzing parallel loops, its approach of taking advantage of the implicit thread struc-
ture of high-level concurrency constructs is also applicable to AsyncTask. We thus extend ITERACE to find races that occur between doInBackground and other threads.

### 5.1 Data Races

Generally, a data race is a pair of accesses, one of which is a write, to the same memory location, with no ordering constraint between the two accesses. For AsyncTask, a data race can occur between accesses in doInBackground and accesses which may execute in parallel with the asynchronous task. While the precise set of instructions that may execute in parallel cannot be determined statically, we can find an approximation of it.

ASYNCRONIZER relies on the Andersen-style static pointer analysis [13] provided by WALA [10]. Thus, our analysis works over an abstract heap built along with a (k-bounded) context-sensitive call graph. The underlying analysis is flow insensitive, except for the limited sensitivity obtained from the SSA form.

Our tool makes the following approximation for a race: instruction $i_a$ in call graph node $n_a$ races with instruction $i_b$ in node $n_b$ if both access the same field of the same abstract object, at least one of the instructions is a write access, and $(n_a, i_a)$ may happen in parallel with $(n_b, i_b)$.

### 5.2 May Happen in Parallel

We now introduce an approximation of the happens-in-parallel relation induced by the AsyncTask. For simplicity, we present the algorithm from the perspective of analyzing the races involving one AsyncTask at a time.

Let $n_b$ be the abstract call graph node for the analyzed doInBackground method. Let $n_b$ be the event handler call graph node which executed $n_b$’s AsyncTask– note that, depending on the choice of abstraction, there can be multiple call graph nodes representing runtime invocations of doInBackground. Let $N_b$ be the set of all the event handler call graph nodes in the current application. For the example in Fig. 3, $n_b$ is the invocation of the doInBackground method on line 2 which led to $n_b$.

Let $i_e$ be the instruction which executes the AsyncTask containing $n_b$. For our example in Fig. 3, $i_e$ is execute method invocation at line 19. Let $n_e$ be the node executing $i_e$. Our choice of context sensitivity ensures its uniqueness.

Let $G^*$ be the so called supergraph [43] having as nodes pairs $(n, i)$, where $n$ is an call graph node, and $i$ is an instruction in $n$. Intra-procedural, i.e., control flow graph (CFG), nodes and edges are lifted to the new graph, with each node $i$ becoming a pair $(n, i)$ and each edge $(i_1, i_2)$ becoming $(n, i_1, i_2)$. Call sites are linked to the lifted CFG of the target call graph node. The call site instruction is represented by two instructions in $G^*$, a call and a return. The call instruction is linked to the entry of the lifted CFG of the target CG node, while the return instruction is linked from the exit. Finally, there is an intraprocedural edge, call-to-return, which bypasses the interprocedural paths by linking the call and the return instructions directly.

Let $G_{c-*}$ be $G^*$ with all its call-to-return edges removed. Figure 5 shows the supergraph without call-to-return edges for the example in Fig. 3. Removing call-to-return edges does not affect reachability but it does affect the dominator relation used below. Call-to-return edges prevent instructions in a called method dominate any instruction after the call.

We say that the instruction $(n_a, i_a)$ may happen in parallel with instruction $(n_b, i_b)$ if $(n_a, i_a)$ is reachable from the doInBackground node $n_b$, and either $(n_b, i_b)$ does not dominate $(n_a, i_a)$ on $G_{c-*}$, or, if $n_b$ calls $n_a$, $i_b$ does not dominate the call to $n_a$ on the $n_b$’s CFG. E.g., in Fig. 5, $(n_a, i_a)$ is the node for line 15 which is within the doInBackground method. $(n_b, i_b)$ is the node for line 4, which does not dominate the forking node (line 19). Thus, the nodes for lines 4 and 17 may happen in parallel.

Furthermore, as the two instructions read and write the same field (mRequestChatId) of the same object (this), they may race. Thus, our tool raises a warning.

### 5.3 Android Model

Android applications are event-based so exercising the code depends on events triggered by the UI, sensors, network, etc. In order to analyze the application statically, ASYNCRONIZER uses a synthetic model of several key Android classes.

Figure 6 shows the callgraph for the code snippet in Fig. 1. ASYNCRONIZER creates synthetic calls between the object initializer (the bytecode <init> method called before the constructor) of an activity or widget and its event handlers. Thus, MainActivity’s initializer calls, among others, onOptionsSelected event handler. Similarly, ASYNCRONIZER puts a synthetic call between a listener’s initializer node to its handlers, and between the an AsyncTask’s execute and its doInBackground. This is an over-approximation of the application’s possible behavior because it may be possible that a particular event will not be triggered. As the analysis is flow insensitive, it does not matter that the handler method is invoked at the handler object initialization point, not at the event trigger point.

ASYNCRONIZER use the following strategy to select entry point for the analysis: (1) if the refactored class itself is an activity, it uses Activity.<init> as entry point; (2) if the refactored class is a GUI widget class (i.e., a View), it uses the object initializer of both the activities who use this widget, and the widget class itself as entry point (i.e., the analysis may run multiple times).
In terms of safety, our analysis is subject to the traditional limitations of static pointer analysis. Aside from the synthetic calls described above, reflection and native code are only handled up to what is provided by the underlying pointer analysis engine, WALA [10]. In some cases, Android apps use reflection to construct objects such as GUI widgets. Our analysis does not analyze such objects. This could be improved by looking into the configuration files used for defining the UI [50]. Also, the analysis’ call graph contains a single node for each event. Considering our may happen in parallel definition, this may lead to false negatives for the cases where an event is invoked repeatedly.

Regarding precision, as our race detection analysis is static, it may report false races. The imprecision stems from various types of imprecision in the underlying pointer analysis. This is currently an unavoidable problem for scalable static race detectors [17,37,41]. First, the pointer analysis may abstract multiple runtime objects by a single abstract object, leading to false warnings on fields of objects that are always distinct at runtime. Second, the analysis is flow-insensitive leading to warnings between accesses that are always ordered at runtime. In particular, our current implementation does not consider event handling order. This leads to some false warnings in our evaluation. For example, the `onCreate` handler is always handled before `onStart`. Thus, an `AsyncTask` started in `onStart` could not happen in parallel with `onCreate`.

6. EVALUATION

To evaluate the usefulness of Asynchronizer we answer the following evaluation questions:

EQ1. Applicability: How applicable is Asynchronizer?

EQ2. Accuracy: How accurate is Asynchronizer when performing the code transformations?

EQ3. Effort: How much programmer effort is saved by Asynchronizer?

EQ4. Safety: Is Asynchronizer safer than manual refactorings?

EQ5. Value: Do programmers find refactorings applied by Asynchronizer useful?

6.1 Experimental Setup

We want to evaluate Asynchronizer on real open-source code, but because we are not the original developers of the code, it is hard to know on which code to apply the refactorings. Thus, we use two sets of experiments. First, we let the source code itself tell us which parts need to be refactored. To do this, we run Asynchronizer on projects that were manually refactored by the open-source developers, and compare the outcomes. Second, we start from the responsiveness issues detected by other researchers [49] and run Asynchronizer on code that was not refactored yet and determine whether the refactorings are useful for the original code developers. We use the first experiment to answer EQ1–EQ4, and the second experiment to answer EQ5.

Replicating existing refactorings. From our formative corpus of 104 projects, we filtered all projects which have at least two manual refactorings from sequential code to concurrent code via Asynctask, thus resulting in a corpus of 13 projects. The left-hand side of Tab. 2 shows the size of each project in non-blank, non-comment source lines of code. For each project, we applied Asynchronizer to the code version just before the version that contained manual refactorings, and we only refactored the same code as the manual refactorings did. Notice that manual refactorings occur in several versions, so we checked out the version we need every time we applied Asynchronizer. We applied Asynchronizer to replicate all 77 manual refactorings in these 13 projects.

We report several metrics for each project. To measure the applicability, we count how many code fragments met the refactoring preconditions and thus can be refactored.

To measure the accuracy of code transformations, we compared the code transformed by Asynchronizer with manually changed code, and report the number of cases that have differences in doInBackground or onPostExecute method. Notice that here we are only interested to compare the code changes (described in Sec. 4), but these changes may still contain data races (we answer safety separately).

To measure the effort that a programmer would spend to refactor the code manually, we report the number of lines and files that are modified by the refactoring. These numbers are a gross estimate of the programmer effort that is saved when refactoring with Asynchronizer. Although we measure effort indirectly, many changes and analysis are non-trivial.

To answer the safety question, we ran Asynchronizer to analyze data races introduced by transformation. Notice that the races which occur in libraries (e.g., JDK) are not reported at that level, but Asynchronizer propagates the accesses up the call graph to the places where the library is invoked from the application [41]. We manually checked all the races and categorize them into four categories: (fixed directly) the races are fixed by developers during their manual refactoring; (fixed later) the races are not fixed during manual refactoring, but are fixed in a later version; (never fixed) the races are not fixed even in the latest version; (false) the races are false warnings.

The races that are fixed directly manifested immediately after a developer first encapsulated code into Asynctask. Since in their commit the developers included both the refactoring and the race fixes, it implies that they are aware of the existence of these races. For the races that are fixed later, we also count how many days on average it took developers to find and fix races, as reported by the time span between the commit that introduces the race and the commit that fixes the races. For the races that are still not fixed in the latest

1We used David Wheeler’s SLOCCount [8] to get size and we only report size of Java code.
Applying new refactorings. The preferred way to test for responsiveness is to run performance tests. However, none of the Android apps that we found had performance tests. Creating performance tests requires domain knowledge, generating test inputs that are representative (e.g., relevant database entries), etc. Thus, to measure the value of the refactoring, we select six projects that have potential responsiveness issues (shown in Tab. 3). These issues are detected in [49] but they have neither been reported, nor fixed.

Notice that these six projects are different from the 104 projects in our formative study. We manually identified the latent long-running operations in main thread. For example, we search for call sites to database APIs in main thread. Then, we applied ASYNCHRONIZER on these operations and generated patches from the refactoring. When ASYNCHRONIZER raised a race warning, we checked and fixed the race. We also included the fix in the refactoring patches. We submitted these patches to developers. In total, we applied ASYNCHRONIZER to 58 places (column Passed + Failed in Tab. 3) in these projects. We grouped all changes and submitted six patches (one patch per project).

6.2 Results

Table 2 tabulates results of applying ASYNCHRONIZER to 13 projects that have manual refactorings.

version, we reported all of them to developers and suggested how to fix them.

After changing the input source code to pass preconditions, we applied ASYNCHRONIZER to these four cases and included them along with the other metrics shown in Tab. 2.

Accuracy: Column 5 shows the number of differences between manual and automated refactorings. The differences do not include other changes made by developers (e.g., adding new features). There is only one case in LibrelidoDev-Android project where the two outputs differ. In this case, manual refactoring moves fewer statements into onPostExecute handler, but they don’t affect the semantics, which means that the code behaves the same way in both cases.

Effort: In total, the refactoring modified 2394 lines of code in 62 files (see LOC Mod. and Files Mod. columns in Tab. 2). On average, each refactoring changes 31 lines of code. More important, many of these changes are non-trivial: programmers need to infer fields, method parameters, and return value, which statements can be moved into onPostExecute, as well as deal with special cases. In contrast, when using ASYNCHRONIZER, the programmer only has to initiate the transformation. ASYNCHRONIZER takes less than 10 seconds per refactoring.

Safety: Columns 8 to 12 show the 134 races that ASYNCHRONIZER detected automatically and we checked manually. Notice that 38 races are not fixed immediately in the manual refactoring, but are fixed in a later version. The strategies to fix these races include adding synchronizations, moving the statements involved in races outside of AsyncTask, changing shared variables into local variables, or removing the shared variables. Interestingly, among these 38 races, 12 races in Allplayers-Android project are fixed incorrectly the first time: developers invoke get immediately after executing the AsyncTask. They applied a second patch to fix them correctly in a later version. In the four projects that fix races in a later version, developers spent 193 days in total to apply patches (Fix Time column). There are 57 false warnings. The reasons for the false warnings were discussed in Sec. 5.3.

The remaining 24 races still exist in the latest version. We reported all of them to developers. They fixed 3 races in Irccloud-Android, and they confirmed 9 races in ChatSecureAndroid and GRTransit. The developers of Sonet do not think the 12 races lead to bugs. In this case, the pair of racing accesses are in two event handlers which develop-
We also check the races reported by Table 3 shows results where we used Value: Testing for mobile apps. Liu et al. [35] empirically study we manually modified the code to satisfy the preconditions.

Our result shows 62 (columns fixed later + never fixed) out of 134 races are neither detected nor fixed when developers perform manual refactoring. Even when they are fixed in a later version, the timespan is long. Thus, Asynchronizer is safer than manual refactoring.

Value: Table 3 shows results where we used Asynchronizer to refactor long-running operations from main thread into AsyncTask. We used a corpus of 6 projects, where in total we applied Asynchronizer to 58 places in 26 files. 56 cases satisfied the preconditions. Similar to the previous experiment, for the two cases that failed the preconditions, we manually modified the code to satisfy the preconditions. We also check the races reported by Asynchronizer (column 5). Notice that the races we show in Tab. 3 do not include false warnings (there are 72 false warnings in total).

We created patches which include the transformations and fixes for races, and submitted the patches to the open-source developers. At the time when this paper is written, the developers from K-9 Mail and KeePassDroid have accepted ten refactorings. The developers of Vudroid and VLC do not think the operations encapsulated into AsyncTask significantly affect UI responsiveness. For example, Vudroid developers said “ZoomRoll class instance is a singleton for application and hence your patch will change only the first time load delay. I have never observed considerable time delays on Activity start”. This shows the importance of having domain knowledge, but also shows that our refactoring approach can produce useful results accepted by developers.

### 7. RELATED WORK

**Testing for mobile apps.** Liu et al. [35] empirically study performance bug patterns in Android apps, and conclude that executing long-running operations in main thread is the main culprit. They also propose an approach to detect such operations statically. Yang et al. [49] test the responsiveness of Android apps by adding a long delay after each heavy API call. Choi et al. [18] use machine learning to learn a model for smartphone apps and generate test inputs from the model. Jensen et al. [29] propose a test generation approach to find event sequences that reach a given target line in smartphone apps. Concolic testing [12] and random testing [28] is also applied to smartphone apps. However, our work is complementary to testing: we enable developers to use AsyncTask refactoring to eliminate the performance issues that are detected in testing.

**Safety analysis of event-driven applications.** Using static analysis, Sai et al. [50] formulate a solution based on call graph reachability to detect GUI accesses from outside the main thread, whereas Zheng et al. [51] target data races due to asynchronous calls for Ajax applications. Recent work on dynamic race detectors for event-driven applications [27, 36, 40, 42] proposed a causality model for JavaScript and Android which they use to infer happens-before relationships between events. Model-checking based techniques have also been proposed for event-driven or GUI applications [14, 24, 46]. In future work, we propose to investigate how the above techniques of modeling event relationships can be integrated with Asynchronizer.

**Empirical studies.** Several researchers studied the usage of libraries, software evolution, and refactoring [15, 16, 30–32, 34, 38, 39]. Kavaler et al. [30] study how programmers ask questions about Android APIs on StackOverflow. Kim et al. [32] studied the benefits of refactoring in industrial code bases. Bavota et al. [15] studied bugs introduced by refactorings. Our previous work [34, 39] shows developers tend to misuse concurrent APIs in Java and C#.

**Refactoring for performance.** Previously, we implemented several refactorings that take advantage of multithreaded parallelism to improve throughput [19–23, 25, 26, 33, 41, 47], and other researchers took similar approaches [44, 45, 48]. However, our current paper focuses on refactoring to retrofit concurrency into Android apps to improve responsiveness.

### 8. CONCLUSIONS

Developers introduce concurrency into programs via concurrent constructs. However, refactoring sequential code to concurrent code is non-trivial, tedious, and error-prone.

We presented a formative study on Android’s AsyncTask. Our study shows that developers use AsyncTask, both to implement new features, and to refactor existing sequential code. However, we found that manual refactoring introduces performance bugs: by misplacing the AsyncTask#get their “concurrent” code runs sequentially. Also we found data races in manually refactored code. In some cases, it took developers hundreds of days to find and fix these bugs.

We presented Asynchronizer, which automates refactoring sequential code to use AsyncTask. The refactoring is composed of two steps: a code transformation that moves user-selected code into AsyncTask, and a safety analysis that checks data races. In our empirical evaluation we applied Asynchronizer on 19 Android apps. We found that the tool is widely applicable, it is accurate compared to manual code transformations, it saves programmers’ effort, it is safer than manual refactoring, and open-source developers accepted several patches with refactorings created by Asynchronizer. This shows that the Asynchronizer is useful.

### 9. ACKNOWLEDGMENTS

We would like to thank Caius Brindescu, Mihai Codoban, Michael Hilton, Semih Okur, Sergey Shmarkatyuk, Chris Scaffidi, and the anonymous reviewers for their feedback on earlier versions of this paper. This research is partly funded through NSF CCF-1439957 and CCF-1442157 grants, a SEIF award from Microsoft, and a gift grant from Intel.
